A B S T R A C T

Acute respiratory distress syndrome (ARDS) is a clinical condition following a diffuse inflammatory insult to the lung parenchyma and generally occurs secondary to a primary disease process. The clinical criteria for ARDS are acute onset of respiratory distress, bilateral pulmonary infiltration on thoracic radiographs, hypoxemia and absence of clinical evidence of left atrial hypertension. Twenty three dogs with ARDS were recruited in this study. Dogs presented with criteria for ARDS had respiratory distress, tachypnea, labored breathing at rest and cyanosis. Blood gas analysis revealed hypoxemia, hypercapnia, hypocapnia, respiratory alkalosis and increased alveolar to arterial oxygen gradient in these cases. Increased pulmonary interstitial and bilateral multilobar alveolar infiltrates were detected in thoracic radiography. This study concluded that ARDS leads to primary and secondary inflammatory changes leads to hypoxemia and abnormal pulmonary infiltrative patterns.

Introduction

Acute respiratory distress syndrome (ARDS) is a clinical syndrome occurs as a result of diffuse inflammatory insult to the lung parenchyma secondary to a primary disease process. The American-European Consensus Conference led to the first broad consensus of definitions in 1994, where ARDS was defined as acute onset of hypoxemia with a ratio of partial pressure of arterial oxygen to fraction of inspired oxygen (PaO_2/FiO_2) 200 mm Hg, with bilateral infiltrates on thoracic radiographs in the absence of left atrial hypertension (Bernard *et al.*, 1994). In 2007, the first clinically based veterinary consensus

definitions on the syndromes of acute lung injury (VetALI) and acute respiratory distress syndrome (VetARDS) were published and effort to improve the validity and reliability of definitions and diagnostic criteria of this condition, the Berlin Definition of ARDS was proposed in 2012. The clinical criteria were established for ARDS by Boiron *et al.,* (2019) included (1) acute onset of respiratory distress, (2) bilateral pulmonary infiltrates on chest radiographs, (3) hypoxemia defined as a PaO_2/FiO_2 (P/F) ratio of ≤300 and in the absence of arterial blood gas analysis, an SpO_2/FiO_2 (S/F) ratio ≤315, and (4) absence of clinical evidence of left atrial hypertension and cases were excluded if thoracic radiographs or echocardiography evidenced left sided congestive heart failure.

Improved understanding of the pathophysiology of ARDS has shown that ARDS is mainly triggered by systemic inflammation which can leads to multiple organ dysfunction syndrome. Several inciting conditions for ARDS have been reported, including trauma, sepsis, pneumonia, pancreatitis, and transfusions (Balakrishnan *et al.,* 2017).

Clinical signs ARDS may be delayed for 2 to 3 days after the inciting event triggers the pulmonary inflammatory response. Manifestations of ARDS may include progressive hypoxemia, respiratory distress, tachypnea and cyanosis. Physical examination observation may include orthopnea, harsh lung sounds progressing to crackles and foamy pink expectorate in severe cases (Declue and Cohn 2007).

Arterial blood gas interpretation and thoracic radiographs are the best indicators of ARDS. Blood gas analysis is mainly important to assess oxygenation, ventilation and acid-base balance thus clarifying the physiological condition of the patient. Blood gas analysis has been documented to be useful in assessing the severity of pulmonary diseases, such as pneumonia, pulmonary fibrosis, and brachycephalic airway syndrome in dogs which triggers the secondary acute respiratory distress syndrome in dogs. Blood gas abnormalities including hypoxemia, respiratory alkalosis and increased alveolar to arterial oxygen gradient are common with this syndrome (Wilkins *et al.,* 2007).

Materials and Methods

Selection of dogs with ARDS

Dogs presented with respiratory emergencies and abnormal paradoxical breathing were subjected to SpO_2 measurement. Blood gas analysis was performed in dogs with SpO_2 less than 90%. Oxygen therapy and thoracic radiography was taken in dogs with PaO_2 less than 80 mmHg. Finally dogs with pulmonary infiltration and PaO_2 less than 60 mmHg were included in this study for further evaluation to identify the primary and systemic risk factors of ARDS. Hematobiochemical and blood smear studies were also performed for the diagnosis of systemic conditions. Ten apparently healthy dogs presented to Madras Veterinary College Teaching Hospital for vaccination and routine health checkup were included as apparently healthy controls.

Arterial blood gas analysis

Blood samples were collected in a heparinised syringe from the femoral artery using a heparinised syringe with caution to avoid air bubbles within the sample and the needle was immediately covered by placing a rubber stopper over the needle tip. Arterial blood was analyzed by blood gas analyzer (EPOC, Siemens) immediately after sample collection. PaO_2 values were classified as normoxemia ($PaO_2 \geq 80$ mmHg), mild hypoxemia ($60 \leq PaO_2 < 80$ mmHg), moderate hypoxemia (45

≤ PaO_2 < 60 mmHg), or severe hypoxemia (PaO_2 < 45 mmHg). $PaCO_2$ values were classified as normocapnia (32 < $PaCO_2$ < 43 mmHg), hypocapnia ($PaCO_2$ ≤ 32 mmHg), hypercapnia ($PaCO_2$ ≥43 mmHg).

Thoracic radiographs

Thoracic radiography of the lungs was performed in dogs after initial stabilization with preoxygenation and mild sedation with butorphanol 0.2 mg/kg administered either intramuscularly or intravenously. Right lateral, left lateral and ventrodorsal radiographs of the thorax were taken. Dogs with pulmonary interstitial and diffuse bilateral pulmonary alveolar infiltrates were taken into study. Whereas cases with radiographic evidences of cardiomegaly or distended pulmonary vessels suggestive of congestive heart failure were not included.

Results and Discussion

Identification of risk factors in the dogs with ARDS

Based on the ARDS criteria mentioned above, twenty three dogs were included in this study and ten apparently healthy dogs served as controls. The risk factors identified for primary ARDS (n=10) were aspiration pneumonia (n=4), pulmonary contusions (n=3), drowning (n=2) and Brachycephalic airway syndrome (BAS) (n=1). Risk factors identified for Systemic ARDS (n=13) were sepsis (n=5) and Systemic Inflammatory Response Syndrome (SIRS) (n=8).

Clinical manifestations

Tachypnea and dyspnea with abnormal paradoxical respiration were observed in all the cases. Crackles and louder breath sounds were observed in dogs with aspiration pneumonia. Dogs with trauma and / or accident had rib fracture and evinced pain during physical examination.

Thoracic radiography

Radiographic changes vary based on the severity and stage of the syndrome. In thoracic radiography diffuse bilateral pulmonary multilobar infiltrates were seen and predominantly caudo dorsal lung lobe infiltrations were observed (Fig 1 and Fig 2)

Arterial blood gas analysis

The findings of the arterial blood gas analysis were presented in the table 1. All the dogs with ARDS showed hypoxemia with hypocapnia or hypercapnia, respiratory alkalosis, metabolic acidosis and increased alveolar to arterial oxygen gradient.

ARDS represents a complex reaction to primary pulmonary and systemic inflammatory factors. The pathological features recorded in ARDS were initial inflammatory or exudative phase followed by a proliferative phase and finally a fibrotic phase (Silversides and Ferguson 2012). ARDS is characterized by high-permeability edema or noncardiogenic pulmonary edema resulting from an increase in extravascular leakage of water from lung parenchyma due to primary pulmonary vascular injury to the endothelium or primary alveolar epithelial injury (Kelmer *et al.,* 2012).

The diagnosis of ARDS is based on clinical criteria and these have been modified in human medicine since the original definition was developed in 1994. In veterinary medicine, the definition of ARDS was published in 2007. Thoracic radiography is the most commonly used tools in veterinary medicine to diagnose pulmonary edema. In this study the presence of pulmonary capillary leak showed bilateral multilobar alveolar

infiltrates without cardiomegaly on thoracic radiographs were observed. A study of human patients reported thoracic radiographs had a sensitivity of 73%, specificity of 70%, and a negative predictive value of 0.47 for ARDS diagnosis (Fan *et al.,* 2018).

Blood gas analysis provide information about both acid-base status and pulmonary function to give the initial stabilization for the patients. Four key values are provided from the arterial blood gas analysis include blood pH, partial pressures of oxygen (PaO_2) and carbon dioxide ($PaCO_2$) and bicarbonate concentration (HCO_3) (Hunter 2001). The normal PaO_2in dog is 80-110 mm Hg. Hypoxemia is defined as a PaO_2 of less than 80 mm Hg at sea level, while a PaO_2 of less than 60 mm Hg is considered severe hypoxemia. Mechanical ventilation is needed for patients with severe hypoxemia despite oxygen therapy or patients with a PaO_2 of less than 60 mm Hg (Hopper and Powell 2013). PaO_2/FiO_2 (PF) ratios were used to determine ARDS in all the dogs. Normal animals breathing room air with an FiO_2 of 0.21 is measured PaO_2 is between 85 and 100 mm Hg, which results in a PF ratio of 400 to 500 (Balakrishnan and Tong, 2020). As a thump rule the normal PaO_2 should be roughly 5 times that of the FiO_2. For example, an animal breathing 50% oxygen should have a normal PaO_2 around 250 mmHg. The PaO_2 ratio for this patient would be 250/0.5, or 500 (Rieser, 2013). In this study patients with ARDS criteria had average PaO_2 value 55 mm Hg in which the PaO_2/FiO_2 ratio (55/0.21 or 261). Pulse oximetry is used as a surrogate for arterial blood gas analysis and the pulse oximetry probe were placed in ear pinna, digits, tongue, tail and skin fold in the abdomen. Preliminary evaluation of the SpO_2/FiO_2 ratio in dogs found that this ratio correlated well with the PaO_2/FiO_2 ratio in a population of dogs requiring assessment of oxygenation (Calabro *et al.,* 2013). In people with ARDS, SpO_2/FiO_2 ratios of 235 and 315 were found to correlate with PaO_2/FiO_2 ratios of 200 and 300, respectively (Rice *et al.,* 2007).

Table.1 Arterial Blood gas analysis of dogs with ARDS

ABG Parameters	Group I Primary ARDS	Group II Systemic ARDS	Group III Apparently healthy dogs	F Value
pH	7.42 ±0.09	7.41 ±0.02	7.39 ±0.06	0.684^{NS}
pCO_2 (mmHg)	21.18 ±0.57^{a}	22.57 ±1.36^{a}	37.34 ±0.82^{b}	60.439**
pO_2 (mmHg)	58.39 ±1.06^{a}	57.62 ±1.35^{a}	90.39 ±0.89^{a}	238.02**
cSO_2	85.63 ±0.51^{a}	86.03 ±0.67^{a}	98.91 ±0.18^{b}	179.26**
A−a gradient(mmHg)	30.37 ± 1.47^{b}	30.97 ± 1.28^{b}	14.21 ± 1.19^{a}	50.941**
PaO_2/FiO_2	252.63 ±24.13^{a}	270.19 ±5.05^{a}	472.76 ±16.19^{b}	69.325**

The values bearing same superscript did not differ significantly.
*p<0.05-significant, **p< 0.01-highly significant and ^{NS} p>0.05-non-significant

Fig.1 Lateral radiographs of the thorax from a dog with acute respiratory distress syndrome. Note the diffuse, severe caudo dorsal lung lobe interstitial to alveolar pattern without signs of cardiac enlargement.

Fig.2 Ventrodorsal radiograph of the thorax from a dog with acute respiratory distress syndrome. Note the bilateral cranial lung lobe alveolar pattern without signs of cardiac enlargement.

The respiratory alkalosis is characterized by a decrease in the $PaCO_2$ concentration results in a compensatory decrease in HCO_3. Common causes of respiratory alkalosis in critically ill dogs include stimulation of peripheral chemoreceptors in response to hypoxemia, pulmonary disease, and direct stimulation of the respiratory center include heatstroke, CNS disease, drugs, sepsis (Proulx, 1999).

Respiratory acidosis is characterized by a decrease in pH and increase in PCO_2 often in conjunction with a compensatory increase in bicarbonate and base excess. Respiratory acidosis is generally the result of respiratory failure and hypoventilation. The main causes of respiratory acidosis include severe pulmonary edema, pulmonary thromboembolism, pneumonia, asthma, chronic obstructive pulmonary disease (McGrotty and Brown, 2013).

Normal physiologic difference in the partial pressure of oxygen in the alveoli (PAO_2) and

the arterial blood (PaO_2) is called as the alveolar to arterial (A-a) gradient (Fanelli *et al.,* 2013). Alveolar-arterial (A-a) gradient can be calculated from arterial blood gas and may help in differentiating the reasons of hypoxemia.

A normal A-a gradient is less than 15 to 25 mm Hg. A-a gradient provide a clinically useful in evaluating the pulmonary parenchymal disease, mainly in situations where the $PaCO_2$ is variable or abnormal when serial blood gases are being compared (Balakrishnan and Tong, 2020). $(A\text{-}a)O_2 = 150 - PaCO_2/0.8$ is the formula used to derive (A-a) gradient.

Blood gas analysis and thoracic radiography is needed for early diagnosis of the syndrome. SIRS, sepsis and aspiration pneumonia were the most common risk factors associated with ARDS, suggesting that earliest diagnosis and therapeutic interventions of sepsis and aspiration pneumonia may reduce the mortalities due to ARDS in dogs.
