ABSTRACT

Salmonellosis is one of the major leading foodborne zoonotic diseases reported worldwide, poultry and poultry products including table eggs were reported as the most important source for foodborne outbreaks in humans. The present study was designed to determine and compare the occurrence of *Salmonella* serovars by cultural and molecular (PCR) methods in processed, unprocessed and desi table eggs available in the markets, resistance pattern of isolates for commonly used antibiotics and decontamination of table eggs using chlorine and peracetic acid. The results of present study revealed that occurrence of *Sal. Enteric* was found to be 5.95 and 9.52 per cent by cultural and PCR method, respectively. Among the isolates obtained, 3.57 per cent was found to be *S. enteritidis* and 2.38 per cent of was *S. typhimurium* serotypes. The occurrence of *S. enterica* was found to be 2.08, 8.33 and 16.67 per cent in processed, unprocessed and desi table eggs, respectively. The MAR indices for all five isolates *Salmonella enterica* was 0.2. Considering the reduction of TVC and *Salmonella* counts from the table egg surface after sanitation, 100 ppm of per acetic acid (PAA) as a sanitizer was comparatively effective than 200 ppm of chlorine (CL). Higher occurrence of *Salmonella* species in the egg is of great public health concern. The study further reinforces the necessity of improving the table eggs before it reaches the consumer.

Introduction

Eggs are one of the economical nutritious food items from the livestock and they form an important part of the routine human diet. However, good qualities of nutrients in eggs offer the suitable environment to the

microbial proliferation. Eggs can be contaminated or infected horizontally (through the shell) or vertically (transovarially), that may become potential source of foodborne diseases in humans (Martelli and Davies, 2011). Some

pathogens like *Salmonella*, *Escherichia coli*, *Camphylobacter spp* and *enterococci* may vertical transmitted (Sreenivasaiah, 2006). Others sources of contamination are through poultry workers, houses or cage, handling during transportation and marketing. Among the egg borne disease Salmonellosis is a major leading disease worldwide. *Salmonella enteritidis* and *Salmonella typhimurium* are the two most important serotypes of *Salmonella* transmitted from animals to human beings. Along with the gastroenteritis they also cause extra intestinal diseases like pleural empyema, meningitis, splenic abscess, meningitis, pleural effusion and osteomyelitis (Sudhaharan *et al.*, 2014). *Salmonella enterica* is a Gram-negative rod-shaped non spore-forming bacterium (Pui *et al.*, 2011). There are around 2,500 known *Salmonellae* serotypes have been documented of which 209 serovars were reported in India (Rahman, 2002). Most commonly used technique for *Salmonella* detection is the conventional or cultural technique and serological tests which are time consuming and labor intensive. Alternatively, PCR technology is employed which is a rapid method with high sensitivity and specificity.

In order to achieve the objective of food safety in modern egg production and processing, sanitization of eggs has become a common practice. Several sanitizers are used for this purpose, such as chlorine (Favier *et al.*, 2001), hydrogen peroxide (Padron, 1995); electrolyzed water (Deza *et al.*, 2003; David *et al.*, 2006; Subrota *et al.*, 2012), UV radiation (Kuo *et al.*, 1997), pulsed light, ozone (Whistler and Sheldon, 1988); gaseous plasma (Luigi *et al.*, 2010) etc., keeping relative merits and limitations in view, chlorine has emerged as one of the best sanitizers used for egg sanitization (Favier *et al.*, 2001). Chlorine exerts its germicidal property by penetrating into the bacterial cell

wall; it interferes with sulfhydryl containing enzymes of glucose metabolism thereby leading to death of bacteria (Banwart, 1979). Similarly per acetic acid also has shown better effect in reducing the bacterial load on food material and also has effective antimicrobial activity in presence of organic matter compared to chlorine (Cruz *et al.*, 2007). Per acetic acid is most commonly used in food processing and handling, sanitizer for food contact surfaces and as a disinfectant for fruits, vegetables, meats, and eggs. It is approved by FDA for use as an indirect food additive (FDA, 2005). So, in the present study peracetic acid is compared with the efficacy chlorine against decontamination of table eggs inoculated with the *Salmonella* Typhimurim isolates.

Table eggs available in the Indian markets were from commercial layer farms and poultry reared in backyard. Portion of eggs from commercial or integrated layer farms which layers are processed, packed and marketed under different brand names (processed) and maximum portion of eggs are marketed through wholesalers/retailers without any brand names (unprocessed). Therefore, in the present study an attempt has been made to determine the occurrence of *Salmonella* serotypes by cultural and PCR methods in the different groups table eggs, antimicrobial resistance pattern of the isolates and comparison of efficacy of PAA (100ppm) with the CL (200ppm) for surface decontamination of table eggs.

Materials and Methods

A total of 840 table egg samples were collected from retail markets of selected districts from Karnataka, India. The samples were collected in a sterile plastic bag and immediately transported to the laboratory. In the present study eggs were categorized into 3 groups, which comprised of processed (480

eggs of 4 different brands- 120 eggs from each brand), unprocessed (240 eggs) and desi eggs (120 eggs). All these egg samples (10 eggs per sample) were analysed for occurrence of *Salmonella enterica* in egg contents. The samples were collected and analysed at four occasions with an interval of 15 days.

Preparation of sample

Ten eggs were selected from each batch and egg surface was sterilized by using 70% ethanol. Then the eggs were broken into a sterile polythene bag. The bags were subjected to homogenization in stomacher (BAG MIXER[®], Interscience) for 2 min to obtain a uniform homogenate.

Occurrence of *Salmonella enteric* by cultural methods

Standard method of isolation of *Salmonella* *i.e.* ISO 6579:2002 was followed in this study. The isolation step involved four stages, non-selective pre-enrichment (buffered peptone water -BPW), selective enrichment (Rappaport-Vassiliadis broth), selective plating (Xylose Lysine Deoxycholate-XLD) and confirmation of *Salmonella* suspected isolates by morphology, motility, biochemical tests and for molecular characterization of isolates, DNA was extracted in the present study by Snap-chill method (Zahrei *et al.*, 2005) followed by determination of virulence markers based on specific amplification of *invA* gene by polymerase chain reaction (PCR) (Rahn *et al.*, 1992). The nucleotide sequences of the forward and reverse amplimers were 5'-GTG AAA TTA TCG CCA CGT TCG GGC AA -3' and 5'-TCA TCG CAC CGT CAA AGG AAC C -3', respectively with amplicon size of 284 bp. Samples were amplified with temperature conditions consisted of an initial 95°C

denaturation step for 1min followed by 35 cycles, with each cycle consisting of 1min at 94°C for denaturation, 1 min at 64 °C for primer annealing, 0.5 min at 72°C for strand elongation and the final cycle at 72°C for 7 min.. PCR products were visualized following electrophoresis through 1.5% agarose gels stained with ethidium bromide.

Electrophoresis

Agarose gel (1.5%) was prepared by heating molecular biology grade agarose in 1 X TAE (Tris Acetate EDTA) buffer so as to dissolve it completely. After cooling to about 50 °C, ethidium bromide (C₂₁H₂₀BrN₃) was added to a final concentration of 1 µg/mL. Molten agarose was then poured into the gel-casting unit and kept undisturbed. After solidification, the comb was removed from the gel. The set gel along with gel-casting unit was submerged in electrophoresis buffer (TAE, 1X). About 4 µl of PCR product was mixed with 1 µl of gel loading dye-6X (10 mM Tris-HCl (pH 7.6) 0.03% bromophenol blue, 0.03% xylene, cyanol FF, 60% glycerol 60 mM EDTA) and loaded into the wells using long micro pipette tips. Simultaneously 100 bp/50bp DNA molecular weight markers were also loaded in one of the wells and electrophoresis was performed at 70 Volts. The progress of mobility was monitored by viewing migration of the dye front. After electrophoresis, the gel was visualized under UV trans-illuminator and gel image was photographed.

Serotyping of *Salmonella enterica*

Sal. enterica isolates that showed positive reactions in biochemical and sugar fermentation tests were further employed for serotyping. All the *Sal. enteric* isolates were sent to National Salmonella and Escherichia Centre, Central Research Institute, Kasauli

(Himachal Pradesh) for serotyping.

Occurrence of *Salmonella enterica* by PCR method

2ml of the pre-enriched samples were centrifuged at 6,000 rpm for 10 min and pellet of the bacterial cells obtained. Pellet was washed with sterile phosphate buffered saline (PBS; pH 7.4) once. The pellet was resuspended in 50µl of nuclease free water and kept in a boiling water bath at 100 °C for 10 min, then transferred immediately to freezer at (-20) °C for 15 min. After freezing, the suspension was centrifuged again at 6,000 rpm for 10 min. The supernatant was collected and used as template DNA for PCR assay (Manoj *et al.*, 2014). PCR products were visualized following electrophoresis through 1.5% agarose gels stained with ethidium bromide and the amplicons were identified based only on the size of the amplified product as explained in paragraph 2.2.

Antibiogram of *S. enteric* isolates

Antimicrobial susceptibility testing was performed by using Kirby-Bauer's disc diffusion method (Bauer *et al.*, 1966) as described by Clinical and Laboratory Standards Institute (CLSI, 2012). All the isolates were tested against 15 antibiotics using antibiotic discs procured from M/s. HiMedia® Ltd., Mumbai. The list of antibiotic discs used and their concentration is given in the Table 2 Multiple Antibiotic Resistance (MAR) index was calculated for each of the isolates obtained to study the spread of antibiotic resistance as described by Kruperman (1983).

Decontamination of table eggs

In the present study 100ppm of PAA and 200ppm CL were selected for sanitary trials against artificially inoculated *S. typhimurium*

on table eggs. Commercially available chlorine tablet (M/s. NICE®) with the available chlorine of 60% and PAA (peracetic acid-5%, hydrogen peroxide-15% and acetic acid 10%) used in the present study. The effective concentration of sanitizers and contact time was selected based on the *in-vitro* studies.

***In-vitro* study**

Efficacy of CL and PAA of different concentrations (i.e., 40, 80, 120, 160 and 200 ppm of CL and 10, 50, 70, 100 and 200ppm of PAA) on *S. typhimurium* at desired concentrations from 10¹ to 10¹⁰ cfu/ml was determined at 3 different contact time i.e., 1, 2.5 and 5 min. The results obtained in the study showed that 200 ppm of CL and 100 ppm of PAA was more effective on the *S. typhimurium* and TVC at the contact time of 2.5 min.

Experimental design for sanitary trials on table eggs

A total of 36 clean and good quality table eggs were collected from the market and used in the experiment. Egg candling was done to remove the cracked and poor shelled eggs. All eggs disinfected with the 70 per cent alcohol. Samples divided into 4 groups with 3 eggs in each group. Groups were divided as a positive control (inoculated), negative control (without inoculated) and 2 test groups each for chlorine and PAA. The trials had been carried out in triplicates. The inoculum was prepared by adding 2-3 *S. typhimurium* colonies from Xylose Lysine Deoxycholate Agar plate into 10 ml of peptone water and incubated at 37 °C for 24 hours. The 24 hour culture was further diluted to required quantity in the ratio of 1:10, so that final concentration of inoculum was approximately 10⁸ cfu/ml and used for surface inoculation.

A 500 ml sterile beaker was taken to which 30

ml of each of fresh culture of *S. typhimurium* (i.e. age of the culture was 24 hours) grown in peptone broth was poured and 270 ml of sterile peptone water was added in order to get a log dilution of 1:10 and thus 300 ml of total volume of the culture was prepared. The table eggs were immersed in the culture for about 10 sec, transferred into the sterile plastic pouches and allowed to be dried for 30 min.

Application of sanitizers to table eggs for decontamination

200 ppm of CL and 100 ppm of PAA were freshly prepared using chlorine free sterile water used in the study. The inoculated table eggs completely immersed in the respective sanitizer (i.e., 200 ppm of CL or 100 ppm PAA) for an effective contact time of 2.5min. After that immediately transferred into the 100 ml of 0.1 per cent peptone water to terminate the effect of sanitizer, this rinsed was used to estimate the TVC and *S. typhimurium* count

Determination of efficacy of sanitizers

The efficacy of the sanitizers for decontamination of eggs determined in terms of total viable count (TVC) and recovery of *S. typhimurium* from the surface of table eggs after decontamination. Spread plate technique was employed to determine the TVC. 0.1 ml of rinsed from treatment and control groups were inoculated on the respective plates and incubated at 37 °C for 24-48 hours followed by recoding the TVC (cfu/ml) after completion of the incubation period.

The recovery of viable *S. typhimurium* was carried out as per the ISO 6579:2002, as explained in paragraph 2.2. Plates were observed for growth of *S. typhimurium* and counts of the organism were enumerated and the log reduction values were derived.

Statistical analysis

Statistical analysis was carried out using MS Excel-2010 and SPSS v20.

Results and Discussion

The present study revealed that, 5.95 per cent of the samples were positive for the presence of *Sal. Enteric* by cultural method. The occurrence of *Sal. enterica* in the processed, unprocessed and desi table eggs were found to be 2.08, 8.33 and 16.67 per cent, respectively.

The biochemical, molecular profiles and serotyping results of *S. enterica* isolates serotyped at National Salmonella and Escherichia Centre, Central Research Institute, Kasauli (Himachal Pradesh) are presented in the Table 1.

Occurrence of *Salmonella enterica* in the table egg samples by PCR technique found to be 9.52 per cent. The occurrence of *Sal. enterica* in the processed, unprocessed and desi table eggs were found to be 2.08, 12.5 and 33.33 per cent, respectively by PCR methods. The results of kappa test had showed the strength of agreement between the tests for *Sal. Enterica* was good (0.751 ± 0.17).

Antibiogram and MAR indices of *Salmonella enterica* Isolates

All the isolates of *S. enterica* (n=5) were sensitive (100%) to ten antibiotics viz. ampicillin, gentamicin, chloramphenicol, cefotaxime, ciprofloxacin, co-trimoxazole, tetracycline, ceftriaxone/tazobactam, nalidixic acid and streptomycin. Varying levels of sensitivity was noticed for neomycin (60 %), cefadroxil (80 %) and cephoxitin (60%) among the different isolates of *S. enterica* (Table 2). All the isolates of *S. enterica* (n=5) were resistant (100%) to cloxacillin and

lincomycin and only one isolate (n=1) showed resistance for neomycin (20 %). Some of the isolates showed intermediate resistance for neomycin (20 %), cefadroxil (20 %) and cephoxitin (40 %). Isolates of *S. enterica* from processed, unprocessed and desi eggs showed 100 per cent resistance to cloxacillin and lincomycin. But for neomycin, isolates of processed and desi egg showed 100 and 50 per cent resistance, respectively. Isolates of unprocessed and desi eggs showed 50 per cent resistance to cephoxitin. All isolates of *S. enterica* from processed, unprocessed and desi eggs were equally sensitive to other antibiotics used in the present study. All (five) isolates of *S. enterica* showed the MAR indices of 0.2.

Efficacy of sanitizers against artificially inoculated *S. typhimurium* and total viable count (TVC) on surface of shell eggs

The effect of sanitizers on total viable count (TVC) assessed and it was observed that the average counts reduced to 3.89 and 3.69 log cfu/ml from an initial count of 6.27 log cfu/ml after treatment with 200 ppm of CL and 100 ppm of PAA, respectively. The average log reductions for 200 ppm of CL and 100 ppm of PAA were recorded as 2.38 (37.73 %) and 2.58 (41.15 %) log cfu/ml, respectively. However, the percentage of log reductions was found to be better for 100 ppm of PAA than 200 ppm of CL in the present study. Likewise, the average initial inoculation (positive control) counts for the *S. typhimurium* on the surface of table eggs was found to be 4.29 log cfu/ml after sanitation achieved 100 per cent reduction *S. typhimurium* from the surface of table eggs. The results of sanitary trials were subjected to statistical analysis and it revealed that both the sanitizers were found to be significantly ($P < 0.05$) effective in reducing the initial TVC.

The table eggs produced and marketed might

vary in their qualities from very good to very poor quality attributes in terms of microbial load. Some pathogens may occasionally present within the egg at the time of lay, but much more commonly it contaminates the liquid egg from the external surface of the shell during storage by penetration or during breaking of the shell. Among the egg borne pathogens *Salmonellae* is one of the commonly isolated which is more pathogenic and transmitted both vertically as well as horizontally. *InvA* gene target was most commonly used for the detection of *Salmonella* in PCR assays (Itoh *et al.*, 1997; Makino *et al.*, 1999 and Wolffs *et al.*, 2006). However, researchers have also reported characterization/detection of *Salmonella* by targeting other genes such as *rfbE*, *fliC*, *virA*, *spvC*, *inT* and *flo* (Itoh *et al.*, 1997; Haqueet *et al.*, 1999; Khan *et al.*, 2000 and Woo *et al.*, 2001, Goelet *et al.*, 2013).

The present study revealed 100 per cent concordance of cultural detection with respect to *invA* gene based on PCR for *Sal. enterica* which were isolated from the table egg samples. Since invasion gene is associated with the pathogenicity or virulence of the *S. enterica*, presence of 284 bp *invA* gene amplicon suggested the occurrence of potentially pathogenic determinants in all the five isolates recovered from table eggs collected from markets. Martelli and Davies (2011) reported that *S. enteritidis* appears to play a major role in egg contamination. *S. enteritidis* was more frequently isolated than *S. typhimurium* from table eggs and these observations are in agreement with the results of present study. The results of the present study is supported by the research of several workers, (Adesiyun *et al.*, 2005; Nagappa *et al.*, 2006; Madhavaprasad, 2009; Assefa *et al.*, 2011; Gole *et al.*, 2013) in a study conducted on quality and safety of raw shell eggs. But, Al-Obaidi *et al.*, (2011) found that higher occurrence of *Salmonella* i.e., 20.0 per cent in table eggs collected from retail stores in

Baghdad and 38.7 per cent in imported eggs, Paul *et al.*, (2016) reported the isolation rate of salmonella was 1.97 percent. In contrary, Safaei *et al.*, (2011) reported zero per cent occurrence of *Salmonella* in table eggs collected from the local markets of Iran.

This study compared the occurrence of *Salmonella enteric* by molecular method i.e., PCR and the conventional culture methods in table egg samples. Most research attempts to establish a method, which can reduce the time required for detection of *Sal. Enteric* from various samples including table eggs (Oliveira *et al.*, 2002; Malorny *et al.*, 2004; Kiranmayi and Krishnainh, 2010). Sensitivity and specificity of PCR is more than cultural methods (Loongyai *et al.*, 2011; Manoj *et al.*, 2014).

In the recent years, there has been a drastic increase in the incidence of drug resistance due to extensive and indiscriminate use of antimicrobial agents for prophylaxis or for growth promotion. The emergence of drug resistant strains follows continued feeding of antimicrobials to layers (Smith and Hall, 1966; Singh *et al.*, 1992). Results of antibiogram in the present study were similar to results reported by Nicodim *et al.*, (2011). In contrary Hassan *et al.*, (2014) reported that isolates of *Sal. enterica* were 100 per cent sensitive to neomycin. Ahmed *et al.*, (2011) reported similar sensitivity pattern (100 %) for chloramphenicol, ampicillin and nalidixic acid against *S. enterica* isolates. Many *Salmonella* isolates exhibited resistance to tetracycline (63.4%), nalidixic acid (63.4%), and streptomycin (61.0%) (Musgrove *et al.*, 2006). The antimicrobial resistance patterns of *Salmonella* vary depending upon the time, region, serovar, the farm practices, breeds and the frequency of antimicrobial agent used (Gyles, 2008). Now a day, wide spread use of antibiotics in poultry production systems is contributing significantly to the increased

antibiotic resistance among the *Salmonella*. The result of present study showed varying degree of resistance to many of the commonly used antibiotics which implies public health concern.

Several researchers have carried out experiments to determine the efficacy of disinfection of table eggs by employing different marker organisms and application of physical or chemical means of disinfection. This study is in accordance with Musgrove *et al.*, (2006) and Favier *et al.*, (2001) who tested the efficacy of 100 ppm of chlorine and found that it was highly effective in reducing of mesophilic aerobic bacteria as at the rate of 4-5 log cfu/egg. Madhavprasad (2009) also reported 62.32 percent reduction of TVC when eggs were treated with 200 ppm of chlorine. Masson (1990) revealed that 2 log cfu/ml reductions in total counts and faecal coliforms on cutsalad mixtures were observed after treatment with 90 ppm of peroxyacetic (peracetic) acid or with 100 ppm of chlorine. Sella *et al.*, (2012) conducted a study to validate the use of peracetic acid as sporicide and reported that the range of MICs was 0.6-1.1 per cent for the control and 0.003-0.006 per cent for the 0.2 per cent peracetic acid solution. Craig and Christine (2014) conducted several experiments to compare the effectiveness of eggshell disinfectants used in the egg industry viz., peracetic acid (PAA), PAA in combination with UV light, and H₂O₂ in combination with UV light; they also reported that peracetic acid was more effective than chlorine but less effective than QAC. In the present study, considering the reduction of TVC and pathogens from the table egg surface after sanitation by 200 ppm of chlorine and 100 ppm of peracetic acid, 100 ppm of peracetic acid as a sanitizer found to be effective than 200 ppm of chlorine as it was able to reduce both TVC and pathogen effectively.

Note: R - Resistant, I – Intermediate, S- Sensitive; P: Processed; UP: Unprocessed; DS: Desi; N-Number of isolates showed resistance

In conclusion, *Salmonella enterica* from layers appeared to be major biosecurity concern in the processed, unprocessed and desi table eggs, which requires sound farm based control measures to ensure safety of table eggs and also constituted a safety concern for consumers, producers and traders. The profile of resistance towards antibiotics reflected the usage of selected antibiotics in different system of the egg production practices. The results of sanitary trials obtained in this study showed that PAA was effective against *Sal. Enteric* as well as TV Con the exterior of shell eggs. Thus, sanitation of eggs immediately prior to breaking should materially reduce contamination of the resultant liquid egg products by microorganisms, especially gram negative bacteria, found on the shell surface. So there is need of proper care in the production practices to produce pathogenic *Sal. Enteric* free eggs and the use of antibiotics should be appropriate so that the wholesome eggs are produced and reaches the consumer.
