An experiment was conducted to study the influence of combinations of different fodder crops on growth and biomass yield under hydroponic condition at Agronomy field unit, Zonal Agricultural Research Station, Gandhi Krishi Vignana Kendra, University of Agricultural Sciences, Bangalore during the year 2018. The experiment was conducted with 13 treatment combinations involving maize, finger millet, little millet and cowpea at different proportions by using completely randomised design (CRD) and repeated three times. The results revealed that 100per cent Maize treatment recorded significantly higher shoot length (19.39 cm), root length (17.61 cm), seedling vigour index (3396), green biomass yield (14.10 kg m<sup>-2</sup>) compared to other treatments.

### Introduction

In India, to meet out the nutritional and economic security for small and marginal farmers livestock plays a major role. The livestock population of India is 512.1 million including 190.9 million cattle (37.27%), 108.1 million buffaloes (21.10%), 65.1 million sheep (12.71%) and 135.2 million goats (26.40%) (Anon., 2017). During last 61 years (1951-2012), the growth rate shows increasing trend in cattle (28.17%), buffaloes (142.7%), sheep (83.01%) and goat (197.7%) population and the overall growth rate in livestock is 80.89% (Anon., 2012). This increasing trend in the livestock population along with the

intensive rearing system has resulted in the increase demands for feeds and fodder in the country. A good fodder supply is required for better livestock production and there is huge gap between demand and supply of green fodder and situation worsen during summer.

The land available for cultivation of green fodder is very limited (only 5% of the gross cropped area); but by 2020, India would require a total 526, 855 and 56 million tons of dry fodder, green fodder and concentrates, respectively (Dikshit and Brithal, 2010). So, there is need for an alternative green fodder production system to meet the demand of the growing livestock population. The best

alternate method for fodder cultivation is hydroponic fodder cultivation. Hydroponic is basically growing plants without soil and the word hydroponic has been derived from the Greek word 'water working'. Hydro means 'water' and ponic means 'working'. It is done either through solution culture (placing the plants in a container of solution), or through medium culture (using another medium such as gravel or sand). It is becoming more and more common in countries where the outdoors is more vulnerable to climate change. It can be practiced in indoors and is more effective this way, as we can control the climate, and ensures a high yield. For arid, dry climates or areas with short growing season hydroponic thus holds a better solution. Further, hydroponics require 1 to 2 litres of water to produce 1 kilogram of fodder when compared to conventional fodder production require 80-90 litres of water to grow 1 kilogram of green fodder. High water productivity is a major advantage of this technique and which saves about 95-97 per cent of water along with land required for fodder cultivation in conventional system (Al-Karaki and Al-Hasimi, 2012). Hydroponics is one of the best ways to get nutritionally rich fodder with high yield over shorter period of time when land available for fodder cultivation is limiting factor.

### **Materials and Methods**

The experiment was conducted at Agronomy field unit, ZARS, University of Agricultural Sciences, GKVK, Bengaluru. It comes under Eastern Dry Zone (Zone-V) of Karnataka situated at latitude of 13.08° N and longitude of 77.59° E with at an altitude of 930 meter above mean sea level. The hydroponic unit was designed with three stands, each of them having width of 75 cm and a height of 170 cm accommodating 5 trays. Each tray was made with vinyl fibre of dimensions 2.5 ft × 1.5 ft × 0.15 ft. Seeds of maize (South African Tall),

finger millet (GPU 48), little millet (JK-8) and cowpea (KBC-2) were weighed and washed with freshwater and then soaked in fresh water for 24 hours in 1:2 proportion (1 part of seeds and 2 parts of water). After 24 hours the water was drained out and the seeds were then tied in a gunny bag and kept in dark. Water was sprinkled at 2-3 hours interval and incubated for another 24 hours for proper germination. After 24 hours, germinated seeds were transferred to trays and covered by wet gunny bag for 2-3 days for better growth and establishment. Later gunny bag was removed and trays were exposed to sunlight and watering was done as and when required. The samples were collected at 5<sup>th</sup>, 10<sup>th</sup> and 14<sup>th</sup> days after sowing for proximate analysis.

The treatment details are T<sub>1</sub>: 100% Finger millet, T<sub>2</sub>: 75% Finger millet + 25% Cowpea, T<sub>3</sub>: 50% Finger millet + 50% Cowpea, T<sub>4</sub>: 25% Finger millet + 75% Cowpea, T<sub>5</sub>: 100% Little millet, T<sub>6</sub>: 75% Little millet + 25% Cowpea, T<sub>7</sub>: 50% Little millet + 50% Cowpea, T<sub>8</sub>: 25% Little millet + 75% Cowpea, T<sub>9</sub>: 100% Maize, T<sub>10</sub>: 75% Maize + 25% Cowpea, T<sub>11</sub>: 50% Maize + 50% Cowpea, T<sub>12</sub>: 25% Maize + 75% Cowpea, T<sub>13</sub>: 100% Cowpea.

The total number of seed germinated was counted in an area of 100 cm<sup>2</sup> from every tray and germination percentage was calculated by using germination percentage formula {Germination (%) = (Number of seeds germinated/Total number of seeds) × 100}.

Biomass yield was taken at 5, 10 and 14 days after sowing. For 5<sup>th</sup> and 10<sup>th</sup> day's observation, biomass yield was measured in weighing machine without harvesting of crops. The crops were finally harvested on 14 days after sowing and biomass yield from each tray was recorded separately in weighing machine as per the treatments. For all

observations, fresh weight was expressed as kg tray<sup>-1</sup> and later converted into kg m<sup>-2</sup>. Dry weight was taken at 5, 10 and 14 days after sowing. After recording the fresh weight, the samples were dried at 65° C until they attain constant dry weight. Dry weight was recorded and expressed in kg m<sup>-2</sup>. The daily added and drained out water from trays throughout the course of experiment were recorded per tray to compute for total water use and water use efficiency or water productivity. The total water used by plants (litres/tray) is calculated using following equation (Al-Ajmi *et al.*, 2009) and expressed in kg/litre.

Total water use = Total water added – Total drained water out of trays

To work out the economics, the market price of seeds and labour unit for the production of hydroponic fodder was considered. Cost of labour was calculated by taking into account the prevailing labour wages at the time of investigation. The prevailing prices of inputs and labour cost were considered for computing the cost of cultivation and expressed in rupees per square meter. Gross return per meter square was calculated by taking into consideration the price of the fresh fodder that was prevailing in the market. Net returns were calculated treatment-wise by deducting cost of cultivation from gross returns.

## **Results and Discussion**

### **Growth parameters and biomass yield attributes of fodder crops as influenced by different treatment combinations**

#### **Germination percentage**

The highest germination percentage was found in 50% Little millet + 50% Cowpea (93.68%) followed by 75% Little millet + 25% Cowpea (93.25%). Lowest germination percentage was recorded in 75% Finger millet

+ 25% Cowpea (91.56%). This was might be due to proper availability of water (moisture), oxygen and temperature to the seeds during the time of pre-germination of seeds before sowing. As well as, those seeds had good viability, high genetic purity, physical purity and less dormancy percentage. The data on germination percentage of different crops as influenced by treatment combinations is presented in table 1.

#### **Shoot length**

At 5 DAS, 100% Maize treatment recorded significantly higher (5.95 cm) shoot length compared to all other treatments and significantly lower shoot length were observed at 100% Little millet (1.78 cm). At 10 DAS, significantly higher shoot length was observed at 100% Maize (15.26 cm) compared to all other treatments. The next best treatment with respect to shoot length is 75% Maize + 25% Cowpea (11.84 cm). Significantly lower shoot length was recorded at 100% Little millet (3.59 cm). At 14 DAS (harvest), 100% Maize treatment recorded significantly higher shoot length (19.39 cm) compared to all other treatments. Significantly lower shoot length was observed at 100% Little millet (4.07 cm). The higher shoot length of 100% Maize may be due to quick establishment, good seedling vigour and fast growth of maize seedlings within short period of time. On the other side, millet seedlings having less seedling vigour index, slow establishment and slow growth with respect to time. Apart from that, the shoot length of 100% Cowpea is moderate as seedling vigour index of cowpea is not as high as of maize. In maize + cowpea treatments, though the maize seedlings having good vigour but due to inter plant competition with cowpea seedlings, the average shoot length of those treatments was less than that of 100% Maize treatment. In those treatment combinations, where the maize proportion is

high, average shoot length was more as in that case maize seedlings can somewhat nullify the dominance of cowpea seedlings. As the proportion of cowpea increases, average shoot length also decreases. In case of millet + cowpea treatments, average shoot length has showed variation due to differential establishment and seedling vigour index of millet and cowpea seedlings. The results are in conformity with the findings of Naik and Singh (2013) and Naik *et al.*, (2016). The data on shoot length (cm) of different crops as influenced by treatment combinations is presented in table 2.

### **Root length**

At 5 DAS 100% Maize treatment recorded significantly higher (5.01 cm) root length compared to rest of the treatments and significantly lower root length was observed at 100% Little millet (1.65 cm). At 10 DAS, significantly higher root length was observed at 100% Maize (13.65 cm) compared to rest of the treatments. Significantly lower root length was recorded at 100% Little millet (3.15 cm). At 14 DAS (harvest), 100% Maize recorded significantly higher root length (17.61 cm) compared to all other treatments and significantly lower root length was observed at 100% Little millet (3.68 cm). The higher root length of 100% Maize may be due to quick establishment, good seedling vigour and fast growth of maize seedlings within short period of time. Root elongation and branching are interactive processes in maize root development which is typically influenced by high seedling vigour. This is in conformity with the findings of Naik and Singh (2013). Variations in the attributes of elongation and branching create morphological differences in root lengths, numbers and diameters of crops. As the maize crop duration is of 14 days, among the embryonic and postembryonic root types, embryonically performed roots (fibrous root)

dominate the seedling root system. On the other side, due to low seedling vigour and slow growth, millet seedlings have given shorter root length. Apart from that, the root length of 100% Cowpea is moderate as seedling vigour index of cowpea is not as high as of maize. Maize and cowpea are having fibrous and tap root respectively. In maize + cowpea treatments, due to dissimilarity of this root systems, both type of seedlings has faced a tremendous inter plant competition than that of their homogeneous condition. Basically, in those treatments, root length of cowpea seedlings is less due to their nature of the root and less seedling vigour. In most of the cases, maize root length growth has overtaken Cowpea root growth, as rate of increase of fibrous root is more than tap root in favourable (sufficient resource) condition. In those treatment combinations, where the maize proportion is high, average root length is more as in that case maize seedlings can somewhat nullify the dominance of cowpea seedlings (3.43, 3.42 and 3.24 cm in 75% Maize + 25% Cowpea, 50% Maize + 50% Cowpea and 25% Maize + 75% Cowpea, respectively at 5 DAS). As the proportion of cowpea increases, average root length also decreases. In case of millet + cowpea treatments, average root length has showed variation due to differential establishment and seedling vigour index of millet and cowpea seedlings. The results are in conformity with the findings of Naik *et al.*, (2016). The data on root length (cm) of different crops as influenced by treatment combinations is presented in table 3.

### **Seedling vigour index**

At 5 DAS, significantly higher seedling vigour index was found in 100% Maize (1007). The next best treatments with respect to seedling vigour are 75% Maize + 25% Cowpea (737) and 50% Maize + 50% Cowpea (730). Significantly lower seedling

vigour index were found in 100% Little millet (315) and 100% Finger millet (357). At 10 DAS, 100% Maize recorded significantly higher seedling vigour index (2,655) compared to rest of the treatments. The next best treatment with respect to seedling vigour index is 75% Maize + 25% Cowpea (2026). Significantly lower seedling vigour was recorded at 100% Little millet (619). At 14 DAS (harvest), 100% Maize recorded significantly higher seedling vigour (3396) compared to all other treatments. Significantly lower seedling vigour index was found in 100% Small millet (713). Seedling vigour index is an important trait for crop establishment and uniform growth of crop. It will influence growth and yield of crop. The seedling vigour is directly correlated to shoot length, root length and germination percentage of crops. Increase in shoot length, root length and germination percentage of the crops are responsible for higher seedling vigour. The increased shoot length and root length of maize in the experiment increased the seedling vigour of 100% Maize treatment as compared to other crops. Though there is not so much variation in germination percentage among the treatments but due to variation in shoot and root length, seedling vigour in each treatment changes drastically. The results are in conformity with the findings of Naik and Singh (2013). The data on seedling vigour index of different crops as influenced by treatment combinations is presented in table 4.

### **Dry weight**

At 5 DAS, 100% Maize recorded significantly higher dry weight (1.85 kg/m<sup>2</sup>) compared to all other treatments. It was at par with 75% Maize + 25% Cowpea (1.76 kg/m<sup>2</sup>). Significantly lower dry weight was observed at 100% Little millet (0.58 kg/m<sup>2</sup>). At 10 DAS, significantly higher dry weight was found in 100% Maize (1.97 kg/m<sup>2</sup>). It was at

par with 75% Maize + 25% Cowpea (1.90 kg/m<sup>2</sup>). Significantly lower dry matter yield was recorded at 100% Little millet (0.90 kg/m<sup>2</sup>). At 14 DAS (harvest), 100% Maize treatment recorded significantly higher dry weight (2.68 kg/m<sup>2</sup>) compared to rest of the treatments. Significantly lower dry weight was found in 100% Little millet (1.24 kg/m<sup>2</sup>). The higher dry weight of 100% Maize is directly related to total dry matter accumulation. Pattern and rate of dry matter accumulation in a crop typically follows a sigmoid curve. Dry weight varies with the different growth stages of the crop. Higher dry matter accumulation during different growth stages of 100% Maize was mainly ascribed to increased photosynthetic ability and their partitioning to different parts with the advancement of age with respect to different treatment combinations. The lower yield of dry matter of millets (100% Little millet and 100% Finger Millet) was might be due to low enzymatic activity in growing plant which led to depletion of food reserves of the seed endosperm resulted in little chance for dry matter accumulation. These results corroborated with the findings of Dung *et al.*, (2010). The data on dry weight (kg/m<sup>2</sup>) of different crops as influenced by treatment combinations is presented in fig. 1.

### **Biomass yield of different fodder crops as influenced by different treatment combinations**

At 5 DAS, 100% Maize treatment recorded significantly higher biomass yield (7.85 kg/m<sup>2</sup>) compared to rest of the treatments. It is on par with 75% Maize + 25% Cowpea (7.62 kg/m<sup>2</sup>). Significantly lower biomass yield was found in 100% Little millet (3.74 kg/m<sup>2</sup>). At 10 DAS, significantly higher biomass yield was observed at 100% Maize (11.75 kg/m<sup>2</sup>) compared to rest of the treatments. Significantly lower biomass yield was recorded at 100% Little millet (7.76

kg/m<sup>2</sup>). At 14 DAS (harvest), 100% Maize treatment recorded significantly higher biomass yield (14.10 kg/m<sup>2</sup>). Significantly lower biomass yield was found in 100% Little millet (9.77 kg/m<sup>2</sup>). Biomass yield is the outcome of different metabolic activities that takes place in the different stages of growth of the plants. Biomass yield of the fodder crop depends on both external and internal factors. Internal factors like growth and yield parameters *viz.*, dry matter accumulation and distribution in different growth stages, fresh and dry weight of the plants, seedling vigour, shoot length and root length and external factors like optimum light, water and nutrients. The increase in dry matter accumulation in seedlings has increased fresh biomass yield of the hydroponically grown maize, finger millet, Little millet and cowpea with respect to time. Here, the higher green biomass yield in 100% Maize might be due to higher yield parameters like fresh weight of shoot and roots, higher growth parameter like shoot length (5.95, 15.26 and 19.39 cm), root

length (5.01, 13.65 and 17.61 cm) and good seedling vigour index (1007, 2,655 and 3,396) at 5 DAS, 10 DAS and 14 DAS, respectively. This is in conformity with the findings of Naik (2012). In comparison to millets and cowpea seeds, maize seeds are large and bold in nature which contains more food and nutrient reserve. This can help maize seedlings to supply the required food for longer period of time and to grow with their maximum potential which ultimately results in significantly higher biomass yield. All the Little millet and finger millet and its associated treatments (with cowpea) has given low biomass yield as compared to maize and its associated (with cowpea) treatments. This was might be due to slow growth of millet seedlings with respect to time, less shoot and root length, low seedling vigour index and less food reserve in their small sized seeds. The data on green biomass yield (kg/m<sup>2</sup>) of different crops as influenced by treatment combinations is presented in table 5.

### Water productivity

At 5 DAS, 100% Finger millet recorded significantly higher water productivity (22.36 kg/litre). Significantly lower water productivity was found in 100% Maize (16.94 kg/litre). Significantly higher water productivity (kg/litre) next to 100% Finger millet was found in 100% Little millet treatment (21.69 kg/litre). At 10 DAS, significantly higher water productivity was found in 100% Finger millet (21.07 kg/litre). The water productivity next to 100% Finger millet were found in 100% Little Millet (20.63 kg/litre) and 75% Finger millet + 25% Cowpea (20.42 kg/litre). At harvest, the water productivity of 100% Finger millet was recorded significantly higher (19.19 kg/litre). Significantly lower water productivity was found in 100% Maize (13.16 kg/litre). All the millets and millet based cowpea treatments has given higher water productivity. This might be due to their less requirement of water compared to other crops taken in this experiment. Side by side, millets have the capability to combat with extreme environmental conditions especially to inadequate moisture or in drought conditions. On the other side, water requirement of maize seedlings is higher than the other crops taken

in the experiment. Cowpea has taken less water than maize but more with compare to millets. For that the treatments having more cowpea proportion with millets has shown less water productivity with compare to 100% Finger millet or 100% Little millet and treatments having more cowpea proportion with maize has shown more water productivity with compare to 100% Maize. In general, water productivity of each treatment has been decreased with respect to time. This was might be due to the increase in dry matter accumulation in seedlings which has increased fresh biomass yield of the hydroponically grown maize, finger millet, Little millet and cowpea with respect to time, hence also the water requirement. The results are in conformation with the results of Mutum Lamnganbi and Surve, (2017). The data on water productivity (kg/litre) of different crops as influenced by treatment combinations is presented in table 6.

### Economics

Among different treatments, 100% Maize recorded higher gross return (Rs.479.4/m<sup>2</sup>) followed by in 75% Maize + 25% Cowpea (Rs.451.1/ m<sup>2</sup>). The lowest gross return has obtained from 100% Little millet (Rs.273.6/

m<sup>2</sup>). 100% Maize recorded higher net return (Rs.344.4/ m<sup>2</sup>) among different treatments taken in experiment followed by in 75% Maize + 25% Cowpea (Rs.309.8/ m<sup>2</sup>). The lowest net return has obtained from 100% Little millet (Rs.138.6/ m<sup>2</sup>). Among different treatments, 100% Maize recorded higher cost benefit ratio (3.55) followed by in 75% Maize + 25% Cowpea (3.19). The lowest cost benefit ratio has obtained from 100% Little millet (2.03). This might be due to the fact that among the crops taken in experiment, maize has given the highest biomass yield with respect to time in comparison to other treatments and market value of maize fodder is also high. So, it has resulted highest gross return. Besides that, fodder maize seed cost is low with respect to other crops. For that it has generated highest net return and cost benefit ratio. The data pertaining to the economics of hydroponic fodder crops viz. maize, finger millet, Little millet and cowpea as influenced by different treatment combinations are presented in table 7.

In conclusion the water and space being limited inputs for fodder production, development of a system that produce high fodder yield is indeed essential at this juncture. Hydroponic fodder production becoming more and more common in countries where the outdoors is more vulnerable to climate change. It can be practiced in indoors and is more effective this way, as we can control the climate, and ensures a high yield. For arid, dry climates or areas with short growing season hydroponic thus holds a better solution. 100% Maize and 75% Maize + 25% Cowpea treatments are best to get higher biomass yield under hydroponic condition. 100% Finger millet, 100% Little millet, 75% Finger millet + 25% Cowpea and 75% Little millet + 25% Cowpea treatments are best to get higher water productivity under hydroponic production system. 100% Maize and 75% Maize + 25%

Cowpea are economically feasible treatments to get higher green fodder yield under hydroponic condition.
