ABSTRACT

Arbuscular mycorrhizal fungi (AM) are known to enhance plant tolerance to a variety of stresses including nutrients, drought, metal toxicity, salinity and pathogens all of which may affect plants success in a contaminated or polluted soil. A study was undertaken to access the influence of paper mill effluents on mycorrhizal colonization and mycorrhizal spore count and regression analyses revealed that the mycorrhizal colonization and mycorrhizal spore count are significantly and positively correlated with various physio-chemical properties in the polluted soil. Glomus was the most dominant isolated mycorrhizal genus of which three dominant species Glomus fasciculatum Glomus macrocarpum, Glomus mosseae have been identified. The study helps us to develop a protocol by studying the association of arbuscular mycorrhizal fungi in plants growing in polluted soil and the potential use of these AM fungi as a future bioremediation agent for rehabilitation of the polluted site contaminated with various trace metals.

Keywords
Arbuscular Mycorrhiza, Trace metals, Phytoremediation, Glomus, Paper mill effluents.

Introduction

Frank (1885) first gave the name Mycorrhiza to describe the essential structure and functioning of the peculiar associations between the roots and ectomycorrhizal fungi. The genera Gigaspora and Scutellospora produce only arbuscules and inter and intracellular hyphae, where as Glomus, Entrophosphora, Acaulospora and Sclerocystis produce vesicles in addition to arbuscules. Arbuscular mycorrhizal (AM) fungi are ubiquitous obligate mycobionts forming symbiosis with the terrestrial plant communities (Barea and Jeffries 1995). The mycosymbionts are widespread among both cultivated and wild plants (Harley and Smith, 1983). So far more than 170 species of AM fungi have been recorded and described (http://invam.caf.wvu.edu/) and many more still awaits discovery. The role of mycorrhizae in plant development pertains to mineral nutrition especially the uptake
of phosphate (Moose 1972). This effect has been attributed to (i) an increase in the absorbing surface and the exploitation of a larger soil volume by the extra radical mycelium, (ii) the small hyphal diameter leading to an increased P absorbing surface area and compared to non-mycorrhizal roots, higher P influx rates per surface unit, (iii) the formation of polyphosphates (Poly P) by mycorrhizal fungi and thus low internal P concentrations, and (iv) the production of organic acids and phosphatases, which catalyze the release of P from organic complexes (Bagyaraj, 1984; Entry et al., 2002; Fomina et al., 2005). The mycorrhizal infection can also increase the uptake of Pb and Mn from soil solutions containing low concentrations of these metals (Heggo et al., 1990; Malcova and Gryndler, 2003).

AM fungi can increase the rate of plant survival, reduce plant stress and increase plant nutrients acquisition, increase carbon and nitrogen deposition into soil (Almas et al., 2004). The metal tolerant AM isolates decrease the metal absorption capacity and filter the intake of metal ions in plants (Martina and Vosatka 2005). The various metal tolerant mycorrhizal fungi have which are found to be evolved as a trace metal-tolerance and thus that they may play important role in the phytoremediation of the site (Liao et al., 2003; Gohre and Paszkowski, 2006; Orłowska et al., 2011; Zarei et al., 2010).

In recent years several studies have shown the harmful effects of metals on microbial diversity and activity in soil (Citterio et al., 2005 and Glassman and Casper 2012). High concentrations of trace metals in soil have an adverse effect on microorganisms. The accumulation of metals in soils at high concentrations can be due to anthropogenic activities such as application of sewage sludge. Addition of sludge increases the amount of trace metals in soil considerably, causing changes in soil properties which could be toxic to both plants and microorganisms. Mycorrhizal fungi that provide a direct link between soil and roots may be of great importance to plants growing in soils contaminated with trace metals (Leyval et al., 1997).

AM are known to enhance plant tolerance to a variety of stresses including nutrients, drought, metal toxicity, salinity and pathogens all of which may affect plants success in a contaminated or polluted soil (Olexa et al., 2000). Glomus was found to be most dominant trace metal tolerant AM fungi isolated from contaminated sludge, as reported earlier by various workers (Joner, 2003; Malcova, 2003).

The pulp and paper mill which has been categorized as one of the twenty most polluting industries in India discharge huge quantities of coloured and waste water (effluent) into the environment and are responsible for soil pollution consequently the hazardous chemicals enter into surface or ground water and poison the soil or crops. There has been continuous decrease of plant diversity due to trace metal soil toxicity by dumping of paper mill effluents through the neighbouring area. Thus, it is very much essential to develop the restoration protocol in the contaminated habitats by use of beneficial rhizosphere fungi like AM fungi that are tolerant to various stresses as they are able to decrease the trace metal absorption capacity and thus considerable increase soil nutrients to the host plant.
Materials and Methods

Location of the study area

The study was conducted at the polluted site inside the campus of Hindustan Paper Corporation Limited, HPC, Assam, India where the solid sludge and effluent have been dumped. The study area was located at an altitude of 116 mMSL between 24052’ N and 92036’ E longitudes.

Collection of soil sample

From the polluted soil, the rhizospheric soil samples were randomly selected and then mixed together to obtain a composited soil representative sample. The soil samplings were done from January 2012 to October 2013 in three seasons, i.e., winter (November to February), summer (March to June) and Monsoon or rainy (July to October). The soil samples were brought to the laboratory in sterile condition and stored in a refrigerator at 4°C until they were processed.

Collection of root samples

Fine roots from plants of the same species were randomly collected and mixed properly and a composited soil root sample was obtained. Trypan blue method was followed for the determination of the intensity of root colonization as described by Phillips and Hayman (1970).

Isolation of Mycorrhizal spores

Spore extraction from the soil was carried out using the Wet Sieving and Decanting Technique by Gerdemann and Nicolson (1963). The isolated spores were mounted on glass slide using Polyvinyl Alcohol-Lactic acid Glycerol (PVLG) and observed under compound microscope (100-1000X). Spores were identified according to the manual of identification of VAM fungi by Schenck and Perez (1990). The INVAM worksheet was used for diagnosing the spores. Additional spores not included in the manual were identified as per the description given in the INVAM websoil (http://invam.caf.wvu.edu/).

Soil Physico-chemical analysis

The physical characteristics of soil i.e., Moisture content, soil pH and soil temperature were estimated for the collected polluted soil samples. The chemical characteristic i.e., N, P, K, Organic C, Mg, Ca etc of the polluted soil samples were estimated using the technique of Jackson (1985). Concentration of trace metals i.e., Cu, Ni and Zn were determined by Atomic Absorption Spectrophotometer (VARIAN Spectra AA 220).

Results and Discussion

The physio-chemical properties of soil were estimated and the maximum moisture content, soil pH, and soil temperature were observed in the rainy seasons followed by summer and winter. The pH was found to be more alkaline in winter seasons in comparison to summer seasons. (Table 1). The all the chemical constituents soil N, K, Organic C (%), Copper (Cu) Nickel (Ni) and Zinc (Zn) were estimated maximum in rainy seasons followed by summer and winter seasons except soil Phosphorus(P), Magnesium (mg) and Calcium (Ca) recorded high values in winter followed by summer and rainy seasons (Table 2). The maximum number of mycorrhizal spore count and percentage of root infection were observed in the rainy seasons followed by summer. In winter seasons, less number of mycorrhizal spore count and low percentage of root infection were reported (Table 3).
Liner regression analyses were calculated to find out the influence of various edaphic factors on mycorrhizal colonization and mycorrhizal spore population. The results of regression analysis showed a positive and significant correlation coefficient (R) values between mycorrhizal spore population with soil moisture content (r = 0.99; P < 0.01; Fig.1(a)), soil temperature (r = 0.96; P < 0.01; Fig. 1(c)), Nitrogen (r = 0.81; P < 0.01; Fig. 1(d)), potassium (r = 0.88; P < 0.01; Fig. 1(f)), Organic carbon (r = 0.95; P < 0.01; Fig. 1(g)), Copper (r = 0.97; P < 0.01; Fig. 1(j)), Zinc (r = 0.97; P < 0.01; Fig. 1(k)) and Nickel (r = 0.97; P < 0.01; Fig. 1(l)).

While the regression values were estimated negative and significant in parameters like soil pH (r = 0.92; P < 0.01; Fig. 1(b)); Phosphorus (r = 0.87; P < 0.01; Fig. 1(e)); Magnesium (r = 0.93; P < 0.01; Fig. 1(h)) and Calcium (r = 0.74; P < 0.01; Fig. 1(i)).

The result of regression analysis showed a positive and significant correlation coefficient (R) values between mycorrhizal colonization with soil moisture content (r = 0.98; P < 0.01; Fig. 2(a)); soil temperature (r = 0.98; P < 0.01; Fig. 2(c)); Nitrogen (r = 0.84; P < 0.01; Fig. 2(d)); potassium (r = 0.90; P < 0.01; Fig. 2(k)); Organic carbon (r = 0.95; P < 0.01; Fig. 2(g)); Copper (r = 0.97; P < 0.01; Fig. 2(g)); Zinc (r = 0.90; P < 0.01; Fig. 2(k)) and Nickel (r = 0.97; P < 0.01; Fig. 2(l)). While the regression values were estimated negative and significant in parameters like soil pH (r = 0.93; P < 0.01; Fig. 2(b)); Phosphorus (r = 0.87; P < 0.01; Fig. 2(e)); Magnesium (r = 0.93; P < 0.01; Fig. 2(h)) and Calcium (r = 0.69; P < 0.01; Fig. 2(i)).

The major keys for identification of isolated *Glomus* spores (Walker, 1983; Mukerji, 1996)

The genus includes both sporocarpic and non-sporocarpic species. The spores are formed at the end of a hypha which may be constricted at the point of attachment to the spore, have parallel side walls, or become markedly occluded at the point of attachment to the spores. The spore wall can have one to many layers, without ornamentation.

**A. Glomus fasciculatum** (Thaxter sensu Gerd.) Gerd. and Trappe

Chlamydospores formed in loose aggregation in sporocarp; 80-120 μm when globose, smooth or rough from adherent debris. Spore wall is 4.2 μm thick, hyaline to yellow, the thicker walls often minutely perforated with thick inward projections, hyphal walls occluded at maturity (Figure 1(A)).

**B. Glomus macrocarpum** Tul. and Tul.

The spores are red brown to dark brown (honey colored), 120-400 μm in width, subtending hypha not inserted, spore without a plug but may be much occluded by lateral walls, spores borne singly, multilayered with cross channels in walls with lignified in growth from outer side of the wall (Figure 1(B)).

**C. Glomus mosseae** (Nicol. and Gerd.) Gerd. and Trappe

Spores rarely filled with hyphae, sporocarp containing 1-10 spores, diameter of subtending hypha at widest part 18-50 μm, outer surface of inner wall is not ornamented; thin, hyaline outer wall may not be obvious.

Figure 1: Mycorrhizal spore population 50gm⁻¹ soil (X) expressed as a function of soil physio-chemical factors (Y) in the polluted soil. Regression is drawn only for statistically significant relationship (p < 0.01). (MC=Moisture Content; Soil temp(C⁰), soil pH, Nitrogen (N), Potassium (K), Phosphorus (P), Organic Carbon (%), Calcium (Ca), Copper (Cu), Zinc (Zn) and Nickel (Ni)).
Figure 2: Mycorrhizal colonization (X) expressed as a function of soil physio-chemical factors (Y) in the polluted soil. Regression is drawn only for statistically significant relationship (p < 0.01). MC=Moisture Content; Soil temp(C), Nitrogen (N), Phosphorous (P), Organic Carbon (%), Calcium (Ca), Magnesium (Mg), Copper (Cu), Nickel Zinc (Zn) and Nickel (Ni)).
Spores are more than 100 μm in size, subtending hypha is generally funnel-shaped with cup-shaped septum (Figure 1(C)).

The present experimental findings revealed the relationship of mycorrhizal spore population and mycorrhizal colonization with various physio-chemical properties of soil polluted with trace metals. The positive and significant regression analysis of mycorrhizal spore population and mycorrhizal root infection is observed with the various physio-chemical properties of soil. The presence of trace metals in the polluted soil may be responsible for less percentage of root colonization in the soil. The high alkalinity, pH and higher soil temperature in the polluted soil is also responsible for decrease in the number of mycorrhizal spores and root infection Schenck and Smith (1982).

AM spore population decreased with increased amount of trace metals in the soil (Val et al., 1999; Hayes et al., 2003). The mycorrhizal root colonization of AMF fungi were found decreased by the higher levels of trace metals in the soil. Our results also supports the findings of (Shah et al., (2010); Biro et al., (2005); Mathur et al.,(2007)).AM vesicles are arbuscules can accumulate various trace metals and can reduce a series of changes in plant physiology, nutrient availability and microbial composition that may determine the outcome of a phytoremediation attempt in the metal-stressed environment.

Among the isolated genera of AM fungi, Glomus was the most dominant AM genus isolated during the present investigation. The dominance of Glomus sp in the polluted soil is due to its higher metal tolerance capacity as reported earlier by various workers (Martina and Vosatka 2005; Schwartz et al., 2006; Chen et al., 2007; Zaefarian et al., 2010; Carrasco et al., 2011). The various metal tolerant mycorrhizal fungi which are found to be evolved as a trace metal-tolerance and thus they can play a very important role in the phytoremediation of the polluted environment.

The above findings suggest that the higher concentrations of physical and chemical properties of the soil are due to the dumping of solid wastes and effluent by the paper mill. The reported indigenous AM isolates are significantly correlated.
with various physic-chemical properties of soil which are able to colonize the plant roots in polluted soil contaminated with various trace metals and higher concentrations of chemical constituents of the soil. So, these AM isolates are adapted to higher concentrations of trace metal and can be used as a combination for inoculation of the plant species growing in the paper mill polluted soil contaminated with trace metals for future bioremediation programmes.
